Chitosan has been considered an environmental-friendly polymer. However, its use in agriculture has not been extended yet due to its relatively low solubility in water. N-Methylene phosphonic chitosan (NMPC) is a water-soluble derivative prepared by adding a phosphonic group to chitosan. This study demonstrates that NMPC has a fungicidal effect on the phytopathogenic fungus *Fusarium solani f. sp. eumartii* (*F. eumartii*) judged by the inhibition of *F. eumartii* mycelial growth and spore germination. NMPC affected fungal membrane permeability, reactive oxygen species production, and cell death. Also, this chitosan-derivative exerted antifungal effects against two other phytopathogens, *Botrytis cinerea*, and *Phytophthora infestans*. NMPC did not affect tomato cell viability at the same doses applied to these phytopathogens to exert fungicide action. In addition to water solubility, the selective biological cytotoxicity of NMPC adds value in its application as an antimicrobial agent in agriculture.

**Keywords** : antifungal activity, *Fusarium solani f. sp. eumartii*, N-methylene phosphonic chitosan derivative, *Solanum lycopersicum*

---

*Fusarium solani f. sp. eumartii* (*F. eumartii*) is a fungus that causes dry potato rot, one of the most economically impacting diseases in the United States, Argentina, Brazil, and Canada. *F. eumartii* infection produces reddish-brown mottling symptoms in tubers between leaf veins and dry rot (Carpenter, 1915). Although *F. eumartii* has been historically considered a potato pathogen, it also infects tomato plants (*Solanum lycopersicum*). Chemical fungicides, such as benzilate and thiabendazole, are frequently used to control fusariosis. However, these fungicides are heavy-duty chemicals that often cause detrimental effects, including pollution and toxicity. Specifically, they produce reproductive and developmental problems in laboratory animals at high oral doses, including skeletal malformations, increased mortality in rats, and multiple anomalies in mice (Gupta, 2018). The resistance of different *Fusarium* spp. against several chemical fungicides has also been previously described (Hou et al., 2018; Qiu et al., 2014; Zhou and Wang, 2001). From all these issues, there is still demand for a more sustainable and eco-friendly type of fungicides and technological improvement to prevent emerging trans-boundary agriculture and food threats, such as pests and diseases (Food and Agriculture Organization of the United Nations, 2017). In this sense, chitosan-based polymers possess proper characteristics since they have not toxicity for...
Chitosan is a linear polysaccharide composed of randomly spread β-(1-4) linked D-glucosamine and N-acetyl-D-glucosamine. This biopolymer displays three functional groups, including primary and secondary hydroxyls and an amine group. It is obtained from chitin which is abundant and easy to isolate from crustacean exoskeletons (Younes and Rinaudo, 2015). Most of the agricultural applications reported for the chitosan has been related to its capacity for the stimulation of plant innate defense mechanisms (Chakraborty et al., 2020) but, also several studies have demonstrated its antimicrobial properties against a set of fungi and bacteria (Duan et al., 2019; Wang et al., 2020). Chitosan is also helpful in controlling the population of plant pathogenic nematodes (El-Sayed and Mahdy, 2015; Fan et al., 2020; Kalaiaresan et al., 2006; Westerdahl et al., 1992). Unfortunately, one disadvantage for its wide use in agriculture is its poor water solubility (de Oliveira Pedro et al., 2013). Therefore, chitosan derivatives compounds have been considered in terms of solubility, gelling, amphiphilic hydrophobic properties, and enhanced biocompatibility when compared to unmodified chitosan (Sahariah & Már Másson). The derivatization has been a widely used procedure to improve the physicochemical properties of chitosan-based compounds (Verlee et al., 2017). The synthesis of O-, N- or N, O-substituted derivatives has been extensively studied (Argüelles-Monal et al., 2018). Heras et al. (2001) described the obtention of the water-soluble N-methylene phosphonic chitosan (NMPC) by reacting chitosan with a phosphonic group. NMPC is soluble in water over a wide range of pH values, and it is a Ca$_{2+}$ and transition metal chelator (Ramos et al., 2003). NMPC was described as a non-viral gene carrier in HeLa cells, indicating its high potential in clinical applications (Zhu et al., 2007). However, so far, it has not been demonstrated to have antimicrobial properties on any pathogenic microorganisms. In this work, we demonstrated the NMPC-mediated antimicrobial action on different phytopathogens such as F. eumartii, Botrytis cinerea, and Phytophthora infestans. In addition, we studied cellular and biochemical downstream events associated with the mode of action of NMPC on the phytopathogen F. eumartii. The antifungal effects on these phytopathogens and the minimal cytotoxicity compared on plant cells suggest that NMPC may be an effective alternative treatment for phytopathogens in agriculture.

**Materials and Methods**

**Biological materials.** Estación Experimental Agropecuaria (EEA) INTA, Balcarce (Argentina) provided the isolated 3122 from F. eumartii (Radtke and Escande, 1973). This fungus was grown on solid potato dextrose agar (PDA; Merck, Darmstadt, Germany) medium at 25°C in darkness. Spores from 8-day-old culture plates were collected and suspended in sterile distilled water (Terrile et al., 2015). B. cinerea strain B05.10 was cultured as described by Benito et al. (1998). P. infestans mating type A2 was grown and preserved on fresh potato tuber slices (Andreu et al., 2010).

Tomato cell suspensions (S. lycopersicum cv. Money Maker, line Msk8) were grown in Murashige-Skoog medium described by Laxalt et al. (2007).

**NMPC preparation.** The chitin, chitosan, and NMPC were prepared as described by Heras et al. (2001). Briefly, chitosan (2% w/v) was dissolved in 1% (v/v) glacial acetic acid. Equals parts of chitosan and phosphorous acid (w/w) were mixed drop-wise with continuous stirring for 1 h. Then, an equal part of 36.5% (w/v) formaldehyde was added drop-wise for an additional 1 h with reflux at 70°C. The clear pale yellow solution was dialyzed against distilled water in dialysis tubing with a cut-off value of 2,500 Da for 48 h or until the pH of the water was raised to 6.8. Finally, the solution was frozen and freeze-dried. The characteristics of NMPC used in this study are 615,595 Da, viscosity 22.5 mPa/seg, substitution degree 1.54, elemental analysis (% C, 34.68; H, 7.10; N, 5.15; P, 7.93. The solubility of NMPC in aqueous media over an extended pH range and its filmogenic nature was verified as previously described (Heras et al., 2001).

**Measurements of spore and sporangium germination.** The antifungal activity of NMPC on F. eumartii and B. cinerea spores and P. infestans sporangia was evaluated as described by Mendieta et al. (2006). F. eumartii (1 × 10^6 spores/ml) and B. cinerea spores (1 × 10^4 spores/ml) and P. infestans sporangia (5 × 10^4 sporangia/ml) were treated with different concentrations of NMPC (0.5, 1, 1.5, 2.5, 5, and 10 µg/ml) in a final volume of 50 µl of 1% sucrose and put on micro slides. The spores of F. eumartii and B. cinerea were incubated at 25°C, while P. infestans sporangia at 18°C for 24 h in darkness. Germinated spores and sporangia were quantified in a hemocytometer under a light microscope Eclipse E200 (Nikon, Tokyo, Japan). We considered spores and sporangia germinated when the germ tube length was longer than one-half of the reproductive structure (Plascencia-Jatomea et al., 2003). We analyzed at least 250 spores or sporangia per replicate, with 3 replicates per treatment. We estimated the IC$_{50}$ values as the concentration of NMPC that reduce germination by 50%.
Inhibition of *F. eumartii* mycelial growth. Final concentrations (5, 50, 100, or 500 µg/ml) of NMPC were incubated with 0.5 cm-diameter disks of PDA agar containing *F. eumartii* mycelia in flasks containing 100 ml of fresh potato dextrose broth medium. *F. eumartii* was grown at 25°C with shaking at 100 rpm in darkness. After 4 days, fungal culture was filtered through muslin to get mycelia and placed in an oven at 65°C for 3 h. The mycelial-dry biomass was measured, and the IC₅₀ value was estimated.

Fungicidal activity on *F. eumartii* cells. *F. eumartii* spores (1 × 10⁶ spores/ml) were treated with 1 and 5 µg/ml of NMPC or distilled water in a final volume of 60 µl. Samples were incubated at 25°C for 24 h in darkness and then spread on PDA. After 3 days, the colonies were counted, and the number of colony-forming units (cfu) was calculated in each sample.

*F. eumartii* cell viability assay. *F. eumartii* cell viability was determined by propidium iodide (PI; Sigma-Aldrich, St. Louis, MO, USA) exclusion as described by Terrile et al. (2015). PI is used to evaluate cell viability as a nucleic acids stain. Once the dye is bound to nucleic acids, its fluorescence is enhanced 20-30-fold (Novo et al., 2000). *F. eumartii* spores (1 × 10⁶ spores/ml) were treated with 1 and 5 µg/ml of NMPC at 25°C for 24 h in darkness. PI was added at a final concentration of 120 µM, and the *F. eumartii* spores were observed in an Eclipse E200 microscope (Nikon) with a G-2/E/C filter set containing an excitation filter at 540/25 nm, suppressor filter at 630/60 nm, and a dichroic mirror at 565 nm.

Membrane permeabilization assay. We detected fungal cells with compromised cell membranes by recording the fluorescence of the DNA-binding dye SYTOX Green (Molecular Probes, Eugene, OR, USA). Permeabilization of the fungal membrane allows the dye to cross the membranes and to intercalate into the DNA. This association displays an intense fluorescence emission when it is excited by blue light illumination (Rioux et al., 2000). The spores were incubated with 5 µg/ml of NMPC or distilled water at 25°C for 1, 2, and 4 h in darkness. Next, 1 µM of SYTOX Green (Invitrogen) was added, and immediately the spores were observed with an Eclipse E200 fluorescence microscope equipped with a B-2 A fluorescein filter set (Nikon).

Measurements of endogenous H₂O₂. The endogenous H₂O₂ level was assessed by peroxidase-dependent staining using 3,3′-diaminobenzidine (DAB; Merck). DAB polymerizes in contact with H₂O₂ in the presence of peroxidase, producing an insoluble colored complex (Thordal-Christensen et al., 1997). *F. eumartii* spores at a final concentration of 1.5 × 10⁶ spores/ml were incubated with 2.5 and 5 µg/ml of NMPC at 25°C for 4 h. Then, 0.5 mg/ml of DAB was added to each sample and incubated for an additional 1 h before rinsing. The spores were observed under an Eclipse E200 light microscope (Nikon).

Tomato cell viability assay. Tomato cell suspensions were grown in Murashige-Skoog medium (Duchefa, Haarlem, The Netherlands) supplemented with 5.4 M naphthalene acetic acid, 1 M 6-benzyladenine, and vitamins (Duchefa) at 24°C with continuous agitation in darkness as described by Laxalt et al. (2007). Tomato cell viability was assayed by Evans blue staining (Sukenik et al., 2018). The cells were incubated with 10 and 100 µg/ml of NMPC at 30°C for 24 h in darkness. As a positive control, cells were treated with 1% Triton X-100 (v/v). Twenty-five µl of 1% Evans blue solution were added to 50 µl of treated-suspension cells, incubated at room temperature for 5 min, and observed under Eclipse E200 light microscope (Nikon). The extent of dye uptake by dead cells was quantified spectrophotometrically by incubating 250 µl of each suspension with 150 µl 1% Evans blue for 5 min at room temperature. Unbound Evans blue stain was removed by washing four times with 0.1 M Tris-HCl pH 7.5. Cells were collected by centrifuging at 800 rpm for 15 s and lysed with 250 µl 100% dimethyl sulfoxide (Sigma-Aldrich) at 100°C for 15 min. The absorbance at 595 nm was measured by using a microplate reader ELx800 (BioTek, Winooski, VT, USA).

Statistical analysis. The values shown in each figure are the mean values ± SD of at least 3 experiments. Data were subjected to analysis of variance (one-way ANOVA) and post hoc comparisons with Tukey’s multiple range test at $P < 0.05$ level. GraphPad Prism 5 (GraphPad Software Inc., San Diego, CA, USA) was used as a statistical software program.

Results
NMPC is an antifungal chitosan derivative. As a first approach to evaluate the antifungal effect of NMPC, we incubated *F. eumartii* and *B. cinerea* spores and *P. infestans* sporangia with different concentrations of NMPC for 24 h. We observed that NMPC inhibited the germination of different cell types in a dose-dependent manner, with almost 100% of spores and sporangia inhibited at 10 µg/ml NMPC (Fig. 1A and B). The estimated IC₅₀ values for *F. eumartii*, *B. cinerea*, and *P. infestans* were 2.5 ± 0.9, 4 ± 1.2, and 2...
Mesas et al. ± 1.3 µg/ml, respectively. The IC₅₀ value of NMPC) on F. eumartii was similar to the IC₅₀ obtained when chitosan was used as control (4.3 ± 2.3 µg/ml) (Supplementary Fig. 1). This fact allowed us to deep into the action of NMPC as a water-soluble and antifungal agent on F. eumartii cells currently used as a phytopathogen model. NMPC caused a significant dose-dependent inhibition of mycelial growth, with a dry mass reduction nearly to 60% at 50 µg/ml of NMPC compared to control (Fig. 2). In this case, the estimated IC₅₀ for mycelial growth was 22 ± 5.2 µg/ml, almost 9 times higher than the estimated IC₅₀ value for F. eumartii spore germination.

To study the fungicidal effect, we incubated F. eumartii spores with different concentrations of NMPC for 24 h and then plated them on an NMPC-free PDA medium for 3 days at 25ºC. Values represent the percentage of colony-forming units compared to control (100%). Each value is the mean ± SD of at least 3 independent experiments. Different letters point out statistically significant differences (Tukey’s test, P < 0.05). Representative images are shown (inset).

**Fig. 1.** Antimicrobial dose-dependent effect of N-methylene phosphonic chitosan (NMPC). (A) The values represent the percentages of total spores/sporangia present in each sample after the incubation with different concentrations of NMPC for 24 h. Each value is the mean ± SD of at least 3 independent experiments. (B) Representative images are shown. Scale bars = 22 µm (upper panels), 15 µm (middle panels), 30 µm (lower panels).

**Fig. 2.** N-Methylene phosphonic chitosan (NMPC) inhibits *Fusarium solani* f. sp. eumartii (F. eumartii) mycelial growth. F. eumartii was inoculated in a liquid potato dextrose broth medium with different concentrations of NMPC and incubated for 4 days. The quantification of the mycelial-dry weight is expressed as the percentage of control (100%). Each value is the mean ± SD of 3 independent experiments. Different letters point out statistically significant differences (Tukey’s test, P < 0.05).

**Fig. 3.** N-Methylene phosphonic chitosan (NMPC) mediates fungicidal action on *Fusarium solani* f. sp. eumartii (F. eumartii) spores. Spores were incubated with 1 or 5 µg/ml NMPC for 24 h and then plated on the Petri dishes containing fresh potato dextrose agar media to allow fungal growth. F. eumartii was grown for 3 days at 25ºC. Values represent the percentage of colony-forming units compared to control (100%). Each value is the mean ± SD of at least 3 independent experiments. Different letters point out statistically significant differences (Tukey’s test, P < 0.05). Representative images are shown (inset).
days. Interestingly, the incubation with 5 µg/ml of NMPC almost abolished fungal growth, suggesting a sensitive NMPC-mediated fungicidal action (Fig. 3). As shown in Fig. 4, while control spores remained unstained by PI, a dose-dependent increase in the percentage of PI-positive spores was observed in NMPC treated *F. eumartii* cells. We detected the highest toxicity (91.3%) at 5 µg/ml NMPC (Fig. 4B).

**NMPC triggers membrane permeabilization and endogenous H$_2$O$_2$ in *F. eumartii* cells.** We analyzed the cell membrane integrity of *F. eumartii* spores by using SYTOX Green. Spores incubated with 5 µg/ml of NMPC during different times were stained with SYTOX Green and subjected to microscopic analysis. Fig. 5A shows that SYTOX Green-mediated fluorescent spores increased over time. While control spores remained virtually unstained, 22% of spores displayed green-fluorescence at 1 h after treatment, and 65% of them were positive for SYTOX Green at 4 h after initial treatment (Fig. 5B). Next, NMPC-mediated cytotoxicity was explored by measuring endogenous H$_2$O$_2$ production in *F. eumartii* spores. The levels of H$_2$O$_2$ gradually increased in a dose-dependent manner by NMPC treatment. After 4 h of 5 µg/ml NMPC treatment, 98% of spores were stained, compared with the untreated control (Fig. 6). These findings indicated that cell membrane permeabilization and H$_2$O$_2$ production are triggered by NMPC.
treatment, and these events could promote the death of *F. eumartii* spores.

**NMPC does not affect tomato cell viability.** Considering NMPC as a putative antimicrobial agent with potential application in plants, we studied its toxicity on tomato cells. We incubated tomato cell suspension cultures with 10 and 100 μg/ml NMPC for 24 h. Then cells were stained with the vital dye Evans blue. The quantification of dye uptake showed that cell viability did not significantly decrease after incubation with 10 and 100 μg/ml NMPC (Fig. 7B). Most tomato cells were unstained with 10 μg/ml NMPC (93%). Even at 100 μg/ml NMPC, the majority of tomato cells excluded the dye (85%), and their morphology remained unchanged (Fig. 7A). However, control cells treated with 1% Triton X-100 showed nuclei and cytoplasm fully stained, and the cell size seemed smaller than those treated either with water or NMPC (Fig. 7A). The viability of cells incubated with Triton X-100 was 7% compared with 98% in untreated cells (Fig. 7B).

**Discussion**

This study demonstrated that NMPC exerted antimicrobial activity on various phytopathogens with agricultural and economic relevance. According to estimated IC<sub>50</sub> values, NMPC displayed antifungal action at similar doses on different pathogens: *F. eumartii*, *B. cinerea*, and *P. infestans*. In particular, NMPC caused cell membrane damage and loss of cel viability on *F. eumartii* spores. Interestingly, NMPC concentrations needed to reach sublethal doses in *F. eumartii* spores were significantly lower than those previously reported for a chitosan N-derivative (Eweis et al., 2006; Liu et al., 2018; Wei et al., 2019; Zhang et al., 2020). Previously, Ippolito et al. (2017) reported that the synthetic fungicide Mancozeb presented antifungal action on *F. eumartii* spore germination. These effects observed with Mancozeb are similar to NMPC antifungal activity on...
F. eumartii. In plants, F. eumartii infection involves spore attachment and germination before host penetration, lesion formation, and tissue maceration (Prins et al., 2000). Thus, the effect of NMPC becomes of particular importance since the progress of the infection to successfully thrive plant tissues needs the efficient germination of spores and the formation of infective hyphae (Laluk and Mengiste, 2010). F. eumartii hyphae proved to be sensitive to the antifungal compound with an estimated IC₅₀ value of 22 µg/ml NMPC. However, F. eumartii spore germination registered an IC₅₀ much lower (2.5 µg/ml), indicating its differential behavior and cell-specific sensitivity. In agreement, mycelium and spores differential sensitivities have been demonstrated for other chitosans (Bautista-Baños et al., 2006; Terrile et al., 2015). The spore germination of F. oxysporum has resulted in more sensitivity to N-derivative chitosan N-2(3)-(dodec-2-enyl) succinyl than hyphal growth, being the IC₅₀ values nearly to 5 µg/ml and 1,000 µg/ml, respectively (Tikhonov et al., 2006). A similar effect on F. oxysporum spore and mycelial treated with six different quaternary N-alkyl chitosan derivatives was also described (Badawy, 2010). An explanation could be that the lipid membrane composition of fungal cells is a crucial point related to sensitivity to chitosan. Feofilova et al. (2015) reported that linoleic acid predominates in mycelial cells while oleic acid is more abundant in spores of different members of the Penicillium genus, supporting the notion that the actively growing fungal cellular structures contain more unsaturated lipids than those under exogenous dormancy. It has been demonstrated that the ratio between oleic and linoleic acids is higher in conidia from F. oxysporum and F. roseum than in mycelia (Rambo and Bean, 1969). Thus, we hypothesized that the differential sensitivity of F. eumartii cells to NMPC could be related to the different lipid compositions of each cell. Palma Guerrero et al. (2010) demonstrated that the plasma membranes of other chitosan-sensitive fungi are more abundant in polyunsaturated fatty acids than chitosan-resistant fungi. A Neurospora crassa mutant with depletion of polyunsaturated fatty acids and reduced membrane fluidity showed increased resistance to chitosan, suggesting that cell permeabilization by chitosan may be dependent on membrane fluidity.

In addition, the mechanism of action of chitosan and derivatives could also be linked to its capacity to chelate certain necessary nutrients, trace elements, and metal ions required for fungal growth (Qin et al., 2008; Rabea et al., 2003). NMPC has an aminoalkyl phosphonic ligand with chelating properties (Heras et al., 2001). Ramos et al. (2003) also proved that NMPC is a powerful chelating agent of Ca²⁺ and other ions. Thus, we cannot discard that NMPC as a chelator compound could also affect Ca²⁺ levels in F. eumartii cells. Kim et al. (2015) demonstrated the Ca²⁺ requirement in fungal developmental processes such as germination, hyphae development, and nutrient uptake. The role of different Ca²⁺ channels in controlling spore germination and hyphal growth in F. oxysporum cells was also demonstrated (Kim et al., 2018). In the same sense, the antimicrobial action against Aspergillus flavus and A. parasiticus correlated with the chelation effect of N-carboxymethyl chitosan by disturbing the uptake of nutritional divalent ions (Cuero et al., 1991). However, whether the potent fungicidal action of NMPC involves chelation of Ca²⁺ or other ions needs to be explored.

In F. eumartii spores, NMPC-mediated cell membrane permeabilization was also concomitant with endogenous ROS production. Thus, cellular H₂O₂ induction may result from the primary effect of cell membrane permeabilization. Moreover, ROS production could cause lipids peroxidation of polyunsaturated fatty acids consequently, inducing cell membrane permeabilization (Howlett and Avery, 1997). In summary, cellular and biochemical events could be responsible for the loss of F. eumartii cell viability mediated by NMPC. Like NMPC, the chitosan derivatives, ATMCs and ATPECS inducted cell membrane damage on F. oxysporum hyphae (Qin et al., 2014). Recently, Lopez-Moya et al. (2021) reported that chitosan induces damages to the plasma membrane in the rice phytopathogen Magnaporthe oryzae and influences NADPH oxidase-dependent synthesis ROS, which is essential for fungal pathogenicity. NMPC could also bind to the negative charge of the membrane surface, causing permeabilization in F. eumartii spores. This fact would be supported by the fact that the current hypothesis that explains the antimicrobial action of chitosan relies on its positive charges that enable electrostatic interactions with the negative charging of the pathogen surface, thus increasing membrane permeability and resulting in cell death (Maluin and Hussein, 2020).

Interestingly, lethal doses of NMPC on F. eumartii did not exert toxicity in tomato cells. Considering the potential of NMPC as a fungicide, its harmlessness to plant cells is a crucial feature. In support of these findings, Asgari-Targhi et al. (2018) analyzed the effect of bulk and nano-chitosan on the growth of the Capsicum annuum. These authors demonstrate that the application of chitosan-based compounds resulted in non-phytotoxic and extended growth of the seedlings. In the same sense, the application of chitosan nanoparticles on wheat and barley showed similar results (Behboudi et al., 2017).

In conclusion, the findings show that NMPC would be...
a promising eco-friendly biofungicide to protect tomato plants against different phytopathogens. Its application could mitigate the broad use of chemical pesticides by ensuring low plant and environmental toxicity.
